MS Thesis Announcement

Interval Bisection Quantization Circuit for an 8-bit Analog to Digital Converter

Colin Taylor

A common type of analog to digital converter (ADC) is called the successive approximation ADC. It works by setting each bit in the digital output code individually and thus its conversion time is determined by the clock frequency and the resolution of the converter. A speed improvement may be made by using a quantization circuit that sets the entire output code at once. The goal of this project is to design such a quantization circuit based on the interval bisection algorithm. The circuit was designed using Cadence Schematic and Virtuoso and was simulated using spice. Spice simulations show that, on average, the circuit converts faster than the conventional successive approximation converter.
